Spike-timing-dependent plasticity (STDP) has been suggested to play a role in the development of functional neuronal connections. However, for STDP to contribute to the synaptic organization, its learning curve should satisfy a requirement that the magnitude of long-term potentiation (LTP) is approximately the same as that of long-term depression (LTD). Without such balance between LTP and LTD, all the synapses are potentiated toward the upper limit or depressed toward the lower limit. Therefore, in this study, we explore the mechanisms by which the LTP/LTD balance in STDP can be modulated adequately. We examine a plasticity model that incorporates an activity-dependent feedback (ADFB) mechanism, wherein LTP induction is suppressed by higher postsynaptic activity. In this model, strengthening an ADFB function gradually decreases the temporal average of the ratio of the magnitude of LTP to that of LTD, whereas enhancing background inhibition augments this ratio. Additionally, correlated inputs can be strengthened or weakened depending on whether the correlation time is shorter or longer than a threshold value, respectively, suggesting that STDP may lead to either Hebbian or anti-Hebbian plasticity outcomes. At an intermediate range of correlation times, the reversal between the two distinct plasticity regimes can occur by changing the level of ADFB modulation and inhibition, providing a physiological mechanism for neurons to select from functionally different forms of learning rules.

1. Introduction

Activity-dependent modification of synaptic transmission, including long-term potentiation (LTP) and long-term depression (LTD), has been widely thought to underlie learning and memory (Bi & Poo, 2001). Although there are various forms of plasticity, recent experiments have revealed that the induction of both LTP and LTD can depend on the relative timing of pre and postsynaptic spikes (Abbott & Nelson, 2000; Bi & Poo, 1998; Caporale & Dan, 2008; Feldman, 2000; Froemke, Poo, & Dan, 2005). In the spike-timing-dependent plasticity (STDP) observed in the neocortical cells, LTP is induced when the presynaptic spike occurs before the postsynaptic spike, while the reversed spike order elicits LTD (Feldman, 2000; Froemke et al., 2005).

An STDP learning rule has been suggested to solve a fundamental problem of unbounded synaptic strengthening in Hebbian learning (Song & Abbott, 2001; Song, Miller, & Abbott, 2000). A Hebbian plasticity rule contributes to the formation of functional circuits and has been used in many neural network studies (Bi & Poo, 2001). Although there are various forms of plasticity, recent experiments have revealed that the induction of both LTP and LTD can depend on the relative timing of pre and postsynaptic spikes (Abbott & Nelson, 2000; Bi & Poo, 1998; Caporale & Dan, 2008; Feldman, 2000; Froemke, Poo, & Dan, 2005). In the spike-timing-dependent plasticity (STDP) observed in the neocortical cells, LTP is induced when the presynaptic spike occurs before the postsynaptic spike, while the reversed spike order elicits LTD (Feldman, 2000; Froemke et al., 2005).

An STDP learning rule has been suggested to solve a fundamental problem of unbounded synaptic strengthening in Hebbian learning (Song & Abbott, 2001; Song, Miller, & Abbott, 2000). A Hebbian plasticity rule contributes to the formation of functional circuits and has been used in many neural network studies (Bi & Poo, 2001). Although there are various forms of plasticity, recent experiments have revealed that the induction of both LTP and LTD can depend on the relative timing of pre and postsynaptic spikes (Abbott & Nelson, 2000; Bi & Poo, 1998; Caporale & Dan, 2008; Feldman, 2000; Froemke, Poo, & Dan, 2005). In the spike-timing-dependent plasticity (STDP) observed in the neocortical cells, LTP is induced when the presynaptic spike occurs before the postsynaptic spike, while the reversed spike order elicits LTD (Feldman, 2000; Froemke et al., 2005).

An STDP learning rule has been suggested to solve a fundamental problem of unbounded synaptic strengthening in Hebbian learning (Song & Abbott, 2001; Song, Miller, & Abbott, 2000). A Hebbian plasticity rule contributes to the formation of functional circuits and has been used in many neural network studies (Bi & Poo, 2001). Although there are various forms of plasticity, recent experiments have revealed that the induction of both LTP and LTD can depend on the relative timing of pre and postsynaptic spikes (Abbott & Nelson, 2000; Bi & Poo, 1998; Caporale & Dan, 2008; Feldman, 2000; Froemke, Poo, & Dan, 2005). In the spike-timing-dependent plasticity (STDP) observed in the neocortical cells, LTP is induced when the presynaptic spike occurs before the postsynaptic spike, while the reversed spike order elicits LTD (Feldman, 2000; Froemke et al., 2005).

An STDP learning rule has been suggested to solve a fundamental problem of unbounded synaptic strengthening in Hebbian learning (Song & Abbott, 2001; Song, Miller, & Abbott, 2000). A Hebbian plasticity rule contributes to the formation of functional circuits and has been used in many neural network studies (Bi & Poo, 2001). Although there are various forms of plasticity, recent experiments have revealed that the induction of both LTP and LTD can depend on the relative timing of pre and postsynaptic spikes (Abbott & Nelson, 2000; Bi & Poo, 1998; Caporale & Dan, 2008; Feldman, 2000; Froemke, Poo, & Dan, 2005). In the spike-timing-dependent plasticity (STDP) observed in the neocortical cells, LTP is induced when the presynaptic spike occurs before the postsynaptic spike, while the reversed spike order elicits LTD (Feldman, 2000; Froemke et al., 2005).
accompanied by an additional mechanism that controls this balance within an adequate range.

Therefore, in this study, we construct a simplified cortical pyramidal neuron model and examine the possible mechanism by which the balance between LTP and LTD in the STDP learning rule can be regulated. Based on the evidence that LTP in STDP depends on postsynaptic NMDA receptors (NMDARs) ([Bender, Bender, Brasser, & Feldman, 2006; Egger, Feldmeyer, & Sakmann, 1999; Nevian & Sakmann, 2006]), which desensitize via the activity-dependent elevation of intracellular Ca\(^{2+}\) ([Legendre, Rosenmund, & Westbrook, 1993; Medina, Leinekugel, & Ben-Ari, 1999; Rosenmund, Feltz, & Westbrook, 1995]), we examine an STDP model, wherein the magnitude of LTP is dynamically modified by such activity-dependent feedback (ADFB) mechanism (Kubota & Kitajima, 2009; Tegnér & Kepes, 2002). We show that in this model, the temporal average of the LTP/LTD ratio can be gradually increased or decreased by enhancing the background inhibition or strengthening the feedback function, respectively. In addition, we demonstrate that in the presence of the ADFB function, but not in the absence, input correlations function to potentiate or depress a group of correlated inputs depending on the time scale of the input correlation. Furthermore, in an intermediate range of correlation time, the modulation of the strength of ADFB as well as of inhibition can regulate whether the correlated inputs become strengthened or weakened by STDP, providing neurons with the ability to govern the direction of the input correlation-based plasticity.

2. Methods

2.1. Neuron model

We used a conductance-based pyramidal neuron model consisting of two compartments representing a soma and a dendrite ([Kubota & Kitajima, submitted for publication]). Both the somatic and dendritic compartments contain voltage-dependent Na\(^{+}\)/K\(^{+}\) currents \((I_{Na} \text{ and } I_{K})\). A voltage-gated Ca\(^{2+}\) current \((I_{Ca})\) and a Ca\(^{2+}\)-dependent potassium current \((I_{K_AHP})\) are incorporated into the dendrite to reproduce spike frequency adaptation found in pyramidal cells ([Ahmed, Anderson, Douglas, Martin, & Whitteridge, 1998]). The amplitude as well as the kinetic parameters for the voltage-gated currents and \(I_{K_AHP}\) have been adjusted such that the model neuron exhibits instantaneous and adapted \(f-I\) curves similar to those of neocortical pyramidal cells ([Kubota & Kitajima, submitted for publication]).

2.2. Synaptic currents

The dendritic compartment receives 4000 excitatory (AMPA and NMDA) and 800 inhibitory (GABA) synapses, each of which follows the conductance-based model given by Kubota and Kitajima (2008) (Fig. 1[A]). The level of inhibitory inputs is assumed to depend on a parameter \(g_{inh}\), which represents the peak conductance of GABA-mediated synaptic currents ([Kubota & Kitajima, 2008]). All the synapses are activated by Poisson processes. The use of Poisson inputs is based on the experimental finding that the spike trains of in vivo cortical cells are highly irregular ([Softky & Koch, 1993]). Excitatory synapses are activated by either uncorrelated spike trains consisting of correlated and uncorrelated ones, while inhibitory synapses are activated by uncorrelated spike trains. All the uncorrelated inputs were generated using independent Poisson spike trains of 3 Hz. Taking into account a relatively lower success rate of synaptic transmission in central synapses (~10%) ([Hessler, Shirke, & Mallnow, 1993]), this input rate corresponds to a presynaptic firing rate of ~30 Hz, which is in the physiologically plausible range for the sensory-evoked responses of cortical neurons. In cases where the input correlation is considered (Figs. 5 and 6), excitatory synapses are assumed to consist of two equally sized groups (2000 for each group) and one group of synapses is activated by correlated spike trains, while the other group is activated by uncorrelated spike trains ([Song & Abbott, 2001]). The presynaptic firing rates for the correlated inputs are generated to have a correlation function that decays exponentially with a time constant \(\tau_c\) (correlation time) ([Song & Abbott, 2001; Song et al., 2000]). The mean (temporally-averaged) firing rate for the correlated inputs is the same as that for the uncorrelated inputs (3 Hz).

2.3. Synaptic weight modification by STDP

STDP is assumed to act on all the excitatory (AMPA) synapses. We denote by \(\Delta t = t_{post} - t_{pre}\) the time lag between the pre and postsynaptic events; positive numbers of \(\Delta t\) imply that the presynaptic event preceded the postsynaptic event. The change in the synaptic weight \(\Delta w\) is described as follows ([Song et al., 2000]) (Fig. 1[B]):

\[
\Delta w = \begin{cases} 
A_+ \exp(-\Delta t/\tau_+), & \text{for } \Delta t > 0, \\
-A_- \exp(\Delta t/\tau_-), & \text{for } \Delta t < 0,
\end{cases}
\]

(1)

where \(A_+ (> 0; \text{see below})\) and \(A_- (=0.004)\) determine the magnitude of synaptic potentiation and depression, respectively, and \(\tau_+ = \tau_- = 20\, \text{ms}\) determines the temporal range over which synaptic strengthening and weakening occur. The value of \(A_+\) corresponds to the relative weight change of 24% when 60 pairs of pre and postsynaptic action potentials take place, as in the case of the physiological experiment of STDP ([Froemke et al., 2005]). When a pre or postsynaptic event occurs, the synaptic weights \(w\) are modified stepwise by an additive updating rule of STDP. The effects of all the pre and postsynaptic spike pairs are linearly summed. Upper and lower bounds \((w_{\text{max}} \text{ and } 0, \text{respectively})\) are imposed on each synaptic weight to stabilize learning dynamics.

![Fig. 1. Components of the computational model. (A) A postsynaptic neuron receives Poisson inputs from both excitatory and inhibitory synapses. The excitatory inputs are plastic and their strength is modified by STDP. (B) The magnitude of LTP in the STDP learning curve is dynamically modulated by feedback depending on postsynaptic firing rate \(f_{post}\) (Eqs. (1) and (2)).](image-url)
2.4. Activity-dependent modulation of LTP

Recent experiments examining STDP (Bender et al., 2006; Egger et al., 1999; Nevean & Sakmann, 1996) have revealed that LTP and LTD involve distinct signaling pathways that may act as coincidence detectors of pre and postsynaptic events: the activation of postsynaptic NMDARs for LTP and that of metabotropic glutamate receptors (mGlus) for LTD. Further, NMDARs have shown to exhibit intracellular Ca\(^{2+}\)-dependent desensitization (Legendre et al., 1993; Medina et al., 1999; Rosenmund et al., 1995), suggesting that LTP, but not LTD, will be suppressed by sustained postsynaptic activity level that results in the accumulation of intracellular Ca\(^{2+}\) (Helchen, Imoto, & Sakmann, 1996; Svoboda, Denk, Kleinfeld, & Tank, 1997). Therefore, we consider ADFB modulation of plasticity such that increased postsynaptic activity decreases the magnitude of LTP: 

\[
A_+(t) = A_+^0 - \alpha f_{\text{post}}(t),
\]

Here, the postsynaptic firing rate at each time point was calculated by 

\[
f_{\text{post}}(t) = \int_0^\infty \lambda \exp(-\lambda t) S_{\text{post}}(t - r) dr,
\]

with the output spike train represented by 

\[
S_{\text{post}}(t) = \sum_{t=0}^{t_{\text{post}}} \delta(t - t_{\text{post}}) \quad \text{and} \quad \lambda = 0.1/s
\]

(Tanabe & Pakdaman, 2001). The parameter values used in the ADFB function itself are 

\[
A_+^0 = 0.008 \quad \text{and} \quad k_{\text{max}} = 0.068 \text{ ms}.
\]

These parameter values were selected such that the postsynaptic firing rate exhibited by our model, including STDP and ADFB, covers a relatively wide range of firing rates observed in neocortical pyramidal cells (60–170 Hz; Fig. 4(D)).

3. Results

3.1. Impact of LTP/LTD balance on learning dynamics by STDP

To investigate how the LTP/LTD balance in the STDP curve affects learning dynamics, we examined the equilibrium properties of the additive STDP rule (i.e., the state where the synaptic weights converge to a stationary distribution) for various values of the LTD size \(A_-\) without ADFB (i.e., \(\alpha = 0\)). In Fig. 2, we plotted the average weight (Fig. 2(A)) and the mean firing rate of the neuron (Fig. 2(B) and (C)) as function of the \(A_+/A_-\) ratio for three different values of inhibitory conductance \(g_{\text{inh}}\). The figure shows that the equilibrium state of STDP changes abruptly over a small range of \(A_+/A_-\) (Rubin et al., 2001; Song et al., 2000). If \(A_+/A_-\) is slightly greater than 1, the synaptic weights are increased toward the upper limit so that the postsynaptic firing rate becomes much higher. Conversely, if \(A_+/A_-\) becomes less than 0.98, the synapses are strongly depressed and, therefore, the postsynaptic activity becomes much lower. On the other hand, the increased level of inhibition (larger \(g_{\text{inh}}\)) can gradually decrease the postsynaptic activity for all values of \(A_+/A_-\) (Fig. 2(B) and (C)). The finding that the neuronal activity is drastically changed in a very narrow range of \(A_+/A_-\) (Fig. 2(C)) implies that to regulate neuronal activity adequately, the LTP/LTD ratio should also be precisely controlled.

To explore the possibility that the ADFB mechanism (Eq. (2)) regulates the LTP/LTD ratio, we simply take the temporal average of Eq. (2) to obtain the following relationship:

\[
\frac{A_+}{A_-}(t) = \frac{A_+^0}{A_-} - \alpha f_{\text{post}}(t).
\]
with \( \alpha = k_{\text{max}} \rho / A_\text{r} \). Here, \( \bar{x}(t) = T^{-1} \int_{t-T}^{t} x(t') \, dt' \) (\( T \gg 1 \)) represents the temporally-averaged value of \( x(t) \). Therefore, \( \bar{x}_{\text{r}} / A_\text{r} - (T) \) is the temporal mean of the LTP/LTD ratio and \( \bar{x}_{\text{post}}(T) \) is the mean firing rate of the postsynaptic neuron. The relationship between \( \bar{x}_{\text{r}} / A_\text{r} - (T) \) and \( \bar{x}_{\text{post}}(T) \) in Eq. (3) was plotted, for given values of \( \rho \), as shown in Fig. 2(B) and (C) (thin lines). If the temporal fluctuation of \( \bar{x}_{\text{r}} / A_\text{r} \) is not so large, it might be expected that the values of \( \bar{x}_{\text{r}} / A_\text{r} - (T) \) and \( \bar{x}_{\text{post}}(T) \) obtained by STDP, in the presence of ADFB modulation, would correspond to the intersection point between 2 different curves – the line representing Eq. (3) for a given \( \rho \) (thin lines) and the postsynaptic rate vs. \( \bar{x}_{\text{r}} / A_\text{r} \) curve (thick lines) for a given \( g_{\text{inh}} \sim \) in Fig. 2(B).

Note that the increase in the strength of ADFB modulation (larger \( \rho \)) will move the intersection point such that the value of \( \bar{x}_{\text{r}} / A_\text{r} \) at this point becomes slightly decreased, as can be seen from Fig. 2(B). This implies the possibility that by changing the parameter \( \rho \), the mean value of the \( \bar{x}_{\text{r}} / A_\text{r} \) ratio at the equilibrium of STDP might be gradually modified within a very small range of \( \bar{x}_{\text{r}} / A_\text{r} \sim 1 \). Moreover, Fig. 2(B) also indicates that the enhanced inhibition (larger \( g_{\text{inh}} \)) would shift the position of the intersection point so that the \( \bar{x}_{\text{r}} / A_\text{r} \) ratio becomes slightly increased. Therefore, in the following section, we examine how the changes in the strength of the ADFB mechanism, as well as the background inhibition level, can regulate the LTP/LTD balance in the STDP curve and thereby influence the learning dynamics.

### 3.2. Control of the LTP/LTD balance through ADFB and inhibitory mechanisms

To explore the role of the ADFB function and inhibition in controlling the LTP/LTD balance, we investigated the equilibrium properties of STDP in the presence of ADFB modulation for various values of \( \rho \) and \( g_{\text{inh}} \). Since the random synaptic activation, as well as the temporal variation in the synaptic distribution, produces fluctuation in the firing activity, the time course of the \( \bar{x}_{\text{r}} / A_\text{r} \) ratio is irregular even at the equilibrium (Fig. 3). However, as the ADFB modulation is facilitated by increasing \( \rho \), the temporally-averaged value of the \( \bar{x}_{\text{r}} / A_\text{r} \) ratio was found to converge to a value slightly smaller than 1 (Fig. 4(A) and (B)), as predicted in Fig. 2(B) (Tegnér & Kepets, 2002). In the presence of this approximate balance in LTP and LTD, a small reduction in the \( \bar{x}_{\text{r}} / A_\text{r} \) ratio considerably decreases the average weight as well as the postsynaptic firing rate (Fig. 4(C) and (D)) (Song et al., 2000). Therefore, the strengthening of ADFB by a further increase in \( \rho \) is counterbalanced by the weakening of the postsynaptic activity, and the temporal average of \( \bar{x}_{\text{r}} / A_\text{r} \) decreases very gradually with increasing \( \rho \) (Fig. 4(D)) (Kubota & Kitajima, submitted for publication).

On the other hand, changing \( g_{\text{inh}} \) does not significantly affect the postsynaptic firing rate for larger \( \rho \) (\( \rho > 0.4 \)) (Fig. 4(D)). Instead, stronger inhibition augments the average weight via a small increase in the LTP/LTD ratio (Fig. 4(B) and (C)). This finding suggests that our model exhibits a strong regulatory function that maintains the excitatory–inhibitory balance through the precise control of the LTP/LTD balance. Furthermore, the coefficient of variation (CV) for the interspike intervals (ISIs) in the output spike train was found to increase with \( \rho \) and \( g_{\text{inh}} \) in the range of larger \( \rho \) values (Fig. 4(E)). The higher ISI variability caused by the enhanced inhibition is attributable to the fact that larger \( g_{\text{inh}} \) increases the average synaptic weight (Fig. 4(C)). This effect reduces the number of excitatory inputs needed to reach the threshold voltage and prevent the temporal integration of inputs from producing regular firing pattern (Softky & Koch, 1993). Although larger \( \rho \) acts to weaken the synapses (Fig. 4(C)), this effect will be overcome by decreasing the postsynaptic firing rate (Fig. 4(D)); since, at lower firing rates, the effective passive decay for the membrane voltage is increased, the neuron will behave as a coincidence detector and thereby can produce an irregular firing pattern (Liu & Wang, 2001).

Additionally, as shown in Fig. 4(B) and (D) (open symbols), we plotted the values of \( \bar{x}_{\text{r}} / A_\text{r} \) and the postsynaptic firing rate corresponding to the intersection points shown in Fig. 2(B) (see Section 3.1), which were calculated by performing the linear interpolation of the firing rate vs. \( \bar{x}_{\text{r}} / A_\text{r} \) relationship for each \( g_{\text{inh}} \) (thick lines in Fig. 2(B)). Fig. 4(B) and (D) indicate that the results obtained by the numerical simulation with the ADFB mechanism (closed symbols) show very good agreement with those predicted by this intersection argument (open symbols).

#### 3.3. ADFB modulation in the presence of correlated inputs

The above results suggest that ADFB may provide STDP with a strong regulatory function such that the postsynaptic firing rate is kept almost constant for a given value of \( \rho \) (Fig. 4(D)).

To examine how such regulatory action affects learning dynamics in the presence of correlated inputs, we divided synapses into two equally-sized groups and introduced correlation into one of them (Song & Abbott, 2001, see Methods). The other group remained uncorrelated so that we could compare the effects of ADFB on the correlated and uncorrelated inputs.

Physiological experiments examining correlated neuronal activity suggest that the time scale of correlation ranges widely from milliseconds to seconds (Bach & Kruger, 1986; Bair, Zohary, & Newsome, 2001; Brivanlou, Warleand, & Meister, 1998; Kohn & Smith, 2005; Lampl, Reichova, & Ferster, 1999; Mastronarde, 1983; Reich, Mechier, & Victor, 2001); the sharing of the same afferent inputs produces correlated spiking on a millisecond time scale (Mastronarde, 1983), whereas the temporal variation in firing activity caused by changing sensory stimuli can generate correlation on a time scale of seconds (Bach & Kruger, 1986; Bair et al., 2001). Therefore, we performed simulations by using a wide range of correlation time \( \tau_c \) (5 ms < \( \tau_c < 5 \) s), the results of which are presented in Fig. 5(A)−(C). Here, to clarify the impact of ADFB, the results of both using and not using ADFB (left and right column, respectively) are shown. The value of \( \bar{x}_{\text{r}} / A_\text{r} \) for the case without ADFB (\( \bar{x}_{\text{r}} / A_\text{r} = 0.975 \)) was chosen such that the steady-state weight distribution becomes approximately the same for the two models with smaller \( \tau_c \) (\( \tau_c = 10 \) ms; Fig. 5(A)). As shown in the figure, with such smaller correlation time, the correlated synapses gather near either the upper or lower boundary, whereas the uncorrelated synapses are depressed toward the lower boundary (Song & Abbott, 2001). However, as the correlation time is increased, all the synapses are pushed toward the lower limit in the absence of ADFB (Fig. 5(B), right), converging to a unimodal distribution, whereas in the presence of ADFB, the correlated and uncorrelated inputs tend to decrease and increase, respectively, converging to a bimodal distribution (Fig. 5(B), left). Therefore, in the presence, but not absence of ADFB, there is a threshold value of \( \tau_c \), such that the correlated inputs are strengthened or weakened, compared to the uncorrelated inputs, depending on whether the value of \( \tau_c \) is smaller or larger than the threshold, respectively (Fig. 5(C) and (D)).
It should be noted that a group of inputs having longer correlation time cannot quit firing after evoking postsynaptic spikes, increasing the number of post–pre-timing spike pairs, which induce LTD (Song et al., 2000). Therefore, it is not surprising that, in both the presence and absence of ADFB, the synaptic strength of correlated inputs was decreased by increasing $\tau_c$ (Fig. 5(C)). An interesting feature of ADFB is that it can function to compensate for the decline of the correlated inputs by increasing the LTP/LTD ratio (Fig. 5(E)). This in turn strengthens the uncorrelated inputs (Fig. 5(C), left), since their synaptic drift is primarily determined by the integral of the STDP curve (Rubin et al., 2001; Song & Abbott, 2001). Thus, the increase in the uncorrelated inputs can counterbalance the decrease in the correlated inputs to maintain the postsynaptic activity (Fig. 5(F)). This will also be understood from Fig. 2(B); the thin lines in this figure, which represents the relationship of Eq. (3), show that ADFB keeps the postsynaptic firing rate at an almost constant value as long as LTP and LTD are approximately balanced.

To further explore the input correlation-based synaptic modifications under the effects of ADFB, we performed similar calculations while changing the strengths of ADFB modulation and of inhibition (Fig. 6). The correlation time dependence of the strength of the correlated and uncorrelated inputs (Fig. 6(A) and (B)) and the difference between them (Fig. 6(C)) as well as the LTP/LTD ratio (Fig. 6(D)) was found to be strongly modified by alterations in $\rho$ and $g_{inh}$. Fig. 6(A) and (B) suggest that the synaptic strength of either both group(s) tends to accumulate very close to the upper or lower limit for a range of very small or large values of $\tau_c$, so that the separation of the two groups of weights becomes saturated under the influence of the boundaries (Fig. 6(C)). The LTP/LTD ratio is increased and decreased, in a wide range of $\tau_c$, by smaller $\rho$ and $g_{inh}$, respectively (Fig. 6(D)), which is consistent with the previous results for uncorrelated input cases (Fig. 4(B)). Additionally, it can be found that in a particular range of $\tau_c$ (80 ms $< \tau_c < 400$ ms), the correlated inputs can be either strengthened or weakened, compared to uncorrelated inputs, depending on the values of $\rho$ and $g_{inh}$ (Fig. 6(C)). This effect implies that the changes in $\rho$ and $g_{inh}$ could regulate which among correlated and uncorrelated inputs become strengthened by STDP. This was clarified by performing the same simulations while systematically changing the values of $\rho$ and $g_{inh}$ in the case of $\tau_c = 160$ ms, as shown in Fig. 6(E). The figure demonstrates that changes in these physiological parameters can modulate both the direction and the magnitude of the input correlation-dependent synaptic modifications emerging from STDP.

4. Discussion

In this study, we have examined an additive STDP model incorporating an ADFB mechanism, wherein higher postsynaptic activity decreases the magnitude of LTP so that the LTP/LTD ratio is modified dynamically. When a postsynaptic neuron received random uncorrelated inputs, the temporal average of the LTP/LTD ratio ($A_+/A_-$) in the STDP curve was increased and decreased gradually, within a range slightly smaller than 1, by increasing $g_{inh}$ and $\rho$, respectively (Figs. 2(B) and 4(B)). The strengths of ADFB and inhibition therefore provide physiological mechanisms by which the LTP/LTD balance in STDP can be precisely controlled. Importantly, for a given value of $\rho$, changing $g_{inh}$ does not significantly change the postsynaptic firing activity (Fig. 4(D)). This finding suggests that ADFB achieves a strong regulatory function that maintains the level of neuronal activity by slightly modulating the LTP/LTD ratio (Fig. 4(B) and (D)). We further studied the cases where the input consists of two groups of synapses, where one group is correlated and the other group is uncorrelated. In this case, as the correlation time ($\tau_c$) was prolonged, the dominant group was switched under ADFB modulation such that the correlated and uncorrelated groups become dominant for smaller and larger $\tau_c$, respectively (Fig. 5(C) (left) and (D)). This switch in the direction of input correlation-based plasticity represents an additional regulatory function emerging from ADFB. When the prolonged correlation weakens the correlated synapses (Fig. 5(C) (left), Song and Abbott (2001)), ADFB can produce a bias in the LTP/LTD ratio toward LTP (Fig. 5(E)) and counterbalance the decrease in the
correlated synapses by the increase in the uncorrelated ones, keeping the neuronal activity nearly constant (Fig. 5(F)). Interestingly, the direction of the input correlation-based plasticity can reverse with changes in the values of $\rho$ and $g_{in}$ within a certain intermediate range of $\tau_c$ (Fig. 6(E)), providing a possible mechanism for tuning a system’s response properties in response to stimulus characteristics.

4.1. Physiological mechanisms regulating LTP/LTD balance in STDP

The synaptic dynamics resulting from additive STDP has been shown to have an important advantage of being competitive, unlike the rate-based models of Hebbian plasticity (Song et al., 2000). However, the induction of such a competitive function critically depends on an approximate balance in LTP and LTD in the STDP curve (Rubin et al., 2001; Song et al., 2000). Considering the fact that such LTP/LTD balance is generally not found in the learning curves obtained by experiments using pairing protocols (e.g. Bi & Poo, 1998), it appears likely that an additional mechanism may be involved in regulating this balance in biological systems.

The present results have shown that the ADFB mechanism can maintain an approximate balance in LTP and LTD in the STDP curve (Rubin et al., 2001; Song et al., 2000). Considering the fact that such LTP/LTD balance is generally not found in the learning curves obtained by experiments using pairing protocols (e.g. Bi & Poo, 1998), it appears likely that an additional mechanism may be involved in regulating this balance in biological systems.

The present results have shown that the ADFB mechanism can maintain an approximate balance in LTP and LTD (Fig. 4(B)); moreover, modulation of the strength of ADFB as well as of inhibition, provided by the activation of GABA conductance, has been found to be effective in very gradually modulating this balance. As mentioned above, a line of evidence suggests that the magnitude of ADFB in cortical neurons can be altered under physiological conditions; first, the induction of LTP, but not LTD,
Fig. 6. The effects of changing the strength of ADFB ($\rho$) and the inhibition level ($g_{inh}$) on the equilibrium properties of STDP in the presence of both correlated and uncorrelated groups of inputs. (A and B) The average weights for the correlated (red) and uncorrelated (black) groups at the equilibrium of STDP are plotted as a function of the correlation time $\tau_c$. In (A), the impact of changing $\rho$ is examined, where $\rho = 0.8$ (solid) or 0.6 (dashed). In (B), the impact of changing $g_{inh}$ is examined, where $g_{inh} = 5$ (thick line) or $3.75 \mu S/cm^2$ (thin line). ($g_{inh} = 5 \mu S/cm^2$ in (A) and $\rho = 0.8$ in (B)). (C and D) The difference in the average weights between the correlated and uncorrelated groups (C) and the temporally-averaged value of $A_+/A_-$ (D) are plotted by using the same line types as those in (A) and (B). (E) The difference in the average weight between the two input groups as a function of $\rho$ and $g_{inh}$, where $\tau_c = 160$ ms. The correlated inputs are potentiated or depressed, as compared to the uncorrelated inputs, depending on the values of $\rho$ and $g_{inh}$.

Importantly, the primary role of the ADFB mechanism in our model is to prevent the saturation of synaptic weights so that the firing rate is maintained in a reasonable range (Fig. 2). Therefore, it would be possible to regulate the LTP/LTD balance by using more general mechanisms that can maintain the firing activity in the neuronal circuits, such as homeostatic plasticity (Turrigiano & Nelson, 2004). Additionally, since the physiological mechanism that provides subunit-specific modulation of NMDAR-mediated synaptic currents (Yuen, Jiang, Chen, Gu, Feng, & Yan, 2005) will be expected to alter the level of ADFB, it appears likely that such mechanism can contribute to regulating the LTP/LTD balance in biological systems. It has also been shown that the LTP/LTD balance can be precisely regulated, similar to the present study, by using the STDP model involving synaptic modification based on a biophysical calcium-dependent plasticity model (Kubota & Kitajima, submitted for publication).

4.2. Hebbian and anti-Hebbian plasticity in STDP

The notion of Hebbian plasticity has guided much work in both experimental and theoretical neuroscience (Buonomano &
STDP has been considered important as a mechanism for realizing Hebbian-based plasticity in natural conditions (Abbott, 2003). STDP can strengthen a group of correlated inputs and promote the organization of neuronal connections in an activity-dependent manner (Song & Abbott, 2001). The present study has revealed that when STDP is accompanied by the ADFB mechanism, it can strengthen or weaken the correlated inputs as compared to uncorrelated ones when the correlation time is shorter or longer than a threshold, respectively (Fig. 5(D)). This result suggests that STDP can act as either a Hebbian or an anti-Hebbian learning rule depending on the correlation structure of afferent inputs. Furthermore, this finding is reminiscent of recent observations of barrel map plasticity (Feldman & Brecht, 2005; Polley, Chen-Bee, & Frostig, 1999; Polley, Kvasnak, & Frostig, 2004), which have revealed that transferring rats from home cages to a natural environment induces the contraction of the representation of frequently-used whiskers as well as the sharpening of the whisker map. Based on our results, we can predict that the contraction of frequently-activated inputs may occur through the appearance of prolonged correlation times within the firing activity of the neuronal subpopulation representing the inputs to the barrel cortex (Fig. 5(D)). Since the time scale of the correlations will significantly depend on that of changing input stimuli (Bach & Kruger, 1986; Simons, 1978), it appears conceivable that the observed change in barrel map plasticity (Polley et al., 1999, 2004) may result from the alteration in the time course of whisker movement caused by active exploration of a natural environment.

Another source of correlated firing arises through synchronized membrane fluctuations, which consist of ‘up’ and ‘down’ states, and is frequently observed between nearby cortical neurons (Anderson, Lampi, Reichova, Carandini, & Ferster, 2000; Castro-Alamancos, in press; Kohn & Smith, 2005; Lampi et al., 1999). The correlation of the two-state membrane potential fluctuation is stronger in pairs of cortical neurons that respond to the same aspects of sensory stimuli (Lampi et al., 1999), and additionally, this type of correlated firing is enhanced by the stimulus presentation (Anderson et al., 2000), suggesting that it plays a role in the stimulus-dependent cortical processing. For a range of correlation time (80–400 ms), nearly corresponding to the time scale of correlation by the membrane potential fluctuation (Anderson et al., 2000; Castro-Alamancos, in press; Lampi et al., 1999), our model predicts that whether the correlated inputs are potentiated or depressed depends on the level of ADFB and GABA inhibition (Fig. 6(E)). Therefore, the combination of the cortical membrane fluctuation and the ADFB modification of STDP may provide the neurons with the ability to select from Hebbian or anti-Hebbian rule such that the inputs arising from sensory stimuli can be strengthened or weakened compared to those from the background spontaneous activity. The cortical network may use Hebbian plasticity to increase the response to the behaviorally important stimuli by strengthening the connections from such stimuli to widely distributed neurons. On the other hand, anti-Hebbian plasticity may be beneficial when animals are in an environment containing many stimuli so that a more efficient method for representing each sensory stimulus is required (Polley et al., 2004). Therefore, we consider that the proposed mechanism for selecting from functionally distinct forms of plasticity rules may be useful to permit efficient distribution of limited metabolic resources for achieving cortical representation of stimuli.
